9 Introduction

It is now clear that species richness tends to increase the temporal stability of biomass production in competitive plant communities. It is even becoming clear that a few core mechanisms related to compensatory dynamics among species through temporal or functional complementarity can explain the positive relationship between diversity and stability. What 13 remains unclear is how the coexistence mechanism that maintains species richness influences 14 the strength of compensatory dynamics. Theoretical studies based on Lotka-Volterra models 15 have given us insight into the mechanisms that promote stability in communities where species 16 coexist by fluctuation-independent mechanisms. A remaining challenge is to explore the 17 importance of proposed mechanisms behind diversity-stability relationships in communities 18 where species coexistence is maintained by temporal variability. Specifically, we seek to 19 understand the mechanisms that promote temporal stability in communities where species coexistence is achieved because of temporal variability.

- To that end, we will analyze a general consumer-resource model under different fluctuation-
- 23 dependent coexistence assmptions. Our starting point is a model of two plant consumers
- 24 and one resource (e.g., soil moisture or nitrogen). We will focus on three cases of species
- 25 coexistence:
- 1. Relative nonlinearty
- 2. Temporal storage effect
- 3. A combination of both mechanisms
- Each scenario requires different model assumptions and structure, so we will describe each
- in turn. Although the structure may change slightly to incorporate different coexistence
- mechanisms, the strength of our approach lies in the similarities among the models since we
- work under a unified consumer-resource framework.

33 Model description and analysis

34 A general consumer-resource model

- 35 We start with a general consumer-resource model where the consumer can be in one of
- two-states: a dormant state D and a live state N (Fig. 1). Transitions between N and D
- occur at discrete intervals T, so our model is formulated as "pulsed differential equations"
- $_{38}$ (Pachepsky et al. 2008, Mailleret and Lemesle 2009). For clarity we refer to T as years and
- the growing time between years, τ , as seasons. Seasonal (within-year) dynamics are modeled
- as three differential equations:

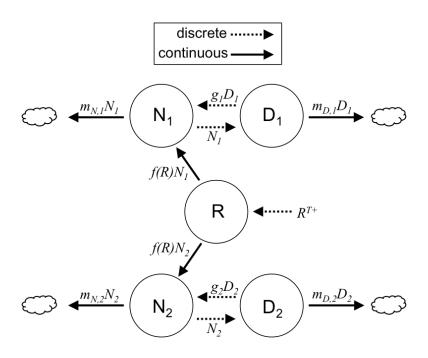

Figure 1: Diagram of our semi-discrete consumer-resource model. Solid lines show continuous dynamics while dashed lines show the discrete transitions.

$$\frac{\mathrm{d}D_i}{\mathrm{d}\tau} = -(m_{D,i}D_i)$$

$$\frac{\mathrm{d}N_i}{\mathrm{d}\tau} = N_i[f_i(R) - m_{N,i}]$$
(2)

$$\frac{\mathrm{d}N_i}{\mathrm{d}\tau} = N_i [f_i(R) - m_{N,i}] \tag{2}$$

$$\frac{\mathrm{d}R_i}{\mathrm{d}\tau} = -\sum_{i=1,2} f_i(R)N_i \tag{3}$$

- where i denotes species, D is the dormant (long-lived) biomass state, N is the living biomass
- (fast-growing, shorter-lived) state, and ms are biomass loss rates. The growth rate of living
- biomass is a resource-dependent function, $f_i(R) = r_i e^{-\alpha_i e^{-\beta_i R}}$. Resource depletion is equal to
- the sum of each species' consumption, $\sum_{i=1,2} f(R)N_i$. Note that since transitions between N
- and D are pulsed, only biomass loss occurs throughout the season for D. 45
- At the beginning of each season we start with initial conditions defined as V_t , W_t , and Z_t for
- the dormant state, the live state, and the resource, respectively. So for each season, Eqs. 1-3 47
- are solved given the initial conditions:

Table 1: Definition of model parameters.

	Table 1: Bennition of model parameters.
Parameter	Definition
m_D	dormant state mortality rate
r	live state maximum resource uptake rate
K	live state half-saturation constant for resource uptake rate
m_N	live state mortality rate
a	resource turnover rate
S	resource supply rate
g	dormant-to-live biomass transition fraction

$$D_i(0) = V_{i,t} \tag{4}$$

$$N_i(0) = W_{i,t} \tag{5}$$

$$R(0) = Z_t (6)$$

- The consumers transition between N and D instantaneously between years. We assume
- resource density does not change between years. So, at the yearly transition:

$$V_{i,t+1} = [N_i(T^-) + D_i(T^-)](1 - g_t)$$
(7)

$$W_{i,t+1} = [N_i(T^-) + D_i(T^-)]g_t$$
(8)

$$Z_{t+1} = R(T^{-}) + R(T^{+}) \tag{9}$$

where $D(T^-)$, $N(T^-)$, and $R(T^-)$ are the densities of each state at the end of the year and g

is a time-fluctuating activation rate that regulates how much dormant biomass is converted to

growing-season live biomass each year. $R(T^+)$ is a randomly generated resource pulse. Our

formulation assumes that at the end of each season all accumulated living biomass $[N(T^{-})]$

is converted to dormant biomass.

57 Implementing the storage effect

To make this a "storage-effect" model, we need to satisfy three conditions: (1) the organisms must have a mechanism for persistence under unfavorable conditions, (2) species must respond differently to environmental conditions, and (3) the effects of competition on a species must be more strongly negative in good years relative to unfavorable years. Our model meets condition 1 because we include a dormant stage with very low death rates. We satisfy condition 2 with our model whenever g is not perfectly correlated between species. Lastly, our model meets condition 3 because condition 2 partitions intraspecific and interspecific competition into different years. Thus, during a high g year for one species, resource uptake is also inherently high for that species, which increases intraspecific competition relative to interspecific competition. So, given adequate variability in g, the inferior competitor (species with lower r) can persist.

Following Adler and Drake (2008), we generated sequences of (un)correlated dormant-to-live state transition rates (g) for each species by drawing from multivariate normal distributions with mean 0 and a variance-covariance matrix of

$$\begin{bmatrix} \sigma_E^2 & \rho \sigma_E^2 \\ \rho \sigma_E^2 & \sigma_E^2 \end{bmatrix} \tag{10}$$

where σ_E^2 is the variance and ρ is the correlation between between the two species' transition rates. For environmental variability, here induced as variability in g, to promote coexistence via the storage effect, ρ must be less than 1. The inferior competitor has the strongest potential to persist when $\rho = -1$ (perfectly uncorrelated transition rates).

⁷⁶ Implementing relative nonlinearity

When considering consumer-resource dynamics, species coexistence by relative nonlinearity requires that each species has different nonlinear responses to resource availability, and resource availability must fluctuate through time. In a constant resource environment, the species with the lowest R* will always exclude the other species. So we can compare this model to the storage effect model, we still allow the germination rate g to vary, but both species are perfectly correlate – that is, $\rho = 1$.

83 Results

84 Storage effect model

- Some preliminary results from running simulations of the storage effect version of the model
- at different levels of environmental cue variability (σ_E) and resource supply variability (σ_S) .
- I ran 20 simulations at each combination of σ_E and σ_S shown in Figure~?? (the points are
- the means across the 20 simulations, each run for 2,000 time-steps, with the initial 1,000
- 59 time-steps discarded before calculating anything). There is a weak trend of community CV
- to saturate at high levels of resource supply variability (Figure~??, top panel).
- One of the things we are interested in is how well the community buffers itself against resource
- 92 variability. Really I should calculate some kind of asynchrony metric, but for now I just
- looked at the ratio of the resource CV to the community CV (Figure~??, bottom panel).
- ⁹⁴ Kind of difficult to interpret, but it is interesting that at high levels of variability in the
- environmental cue that drives the storage effect, the ratio decreases with resource supply
- yariability. The opposite occurs at lower levels of variability in the environmental cue.
